FIELD OF THE INVENTION

[0001] This invention generally relates to changing the bandwidth between a device and a processor. More particularly this invention relates to an apparatus and method capable of changing the bandwidth between a device and a processor without changing the physical component layout in the processor.

BACKGROUND OF THE INVENTION

[0002] Joining several processors in parallel increases processing capacity. Typically, any number from two to eight processors may be joined in parallel. Generally, multiple parallel processors are joined together on a shared bus. Figure 1 illustrates a four processor (4P) architecture used in conjunction with a shared bus. Four processors, Processor 1, Processor 2, Processor 3, and Processor 4, connect to a shared bus, which in turn connects to the Northbridge chipset. The Northbridge chipset further connects to the Southbridge chipset and external memory. For example, a Pentium™ processor may employ the shared bus architecture illustrated in figure 1. However, a point-to point architecture, typically, provides a higher bandwidth than does a shared bus architecture.

[0003] In a shared bus architecture, multiple devices all share the same bus and must follow an order and protocol to use the bus. In contrast, a point-to-point bus architecture provides an uninterrupted connection between two separate devices. Thus, in general, a point-to-point bus creates a higher bandwidth between two separate devices. A higher bandwidth can have the

beneficial effect of yielding an increased performance from a single processor or group of processors. For example, if a 48-bit connection exists between two devices, then transactions occur between the two device three times faster than if only a 16-bit connection exists between the two devices. However, a point-to-point bus architecture may have a disadvantage because the architecture provides an uninterrupted connection between two separate devices. Thus, if at any given time, light transfers of information occur between the two devices, then the excess bandwidth capacity is essentially wasted.

[0004] For example, if a customer is using his or her computer system to run both a workstation application and a server application, then the customer may not be achieving peak performance from the hardware in his computer system. In a server application a heavy exchange of information occurs between processors. Thus, the manufacturer creates a high bandwidth connection between each processor in the system. Yet, if for example a customer wants to use his computer system for an application, which involves a heavy exchange of information between processors and a chipset, such as a workstation application, then the manufacturer creates a high bandwidth connection between each processor and the chip in the system. However, if the customer has a computer system which has a high bandwidth connection between the processor(s) and the chipset, but chooses to currently run a server application on this system, then the customer may suffer poor performance from the server application and waste the excess bandwidth between the chipset and processor(s).

[0015] While the invention is subject to various modifications and alternative forms, specific embodiments thereof have been shown by way of example in the drawings and will herein be described in detail. The invention should be understood to not be limited to the particular forms disclosed, but on the contrary, the intention is to cover all modifications, equivalents, and alternatives falling within the spirit and scope of the invention.

[illegible][illegible]

[0018] Figure 2 illustrates an embodiment of a processor **200** having a routing agent **202**, a protocol layer **204**, a buffer layer **206**, and an information transfer layer **208**. In one embodiment, the processor **200** has a routing agent **202** and three layers, the protocol layer **204**, a buffer layer **206** such as one or more link layers **210**, and an information transfer layer **208** such as one or more physical layers **212**. The routing agent **202** changes the communication pathways within the physical layer **212** and link layer **210** without changing the physical component layout in the processor **200**. The physical layer **212** carries out the actual physical transfer of information to and from other devices. The link layer **210** performs liaison functions between the higher functions of the protocol layer **204** and the physical layer **212**. The protocol layer **204** processes requests, responses, and data transfers.

[0019] In an embodiment, the routing agent **202** may be internal or external to the processor **200**. In an embodiment, a single routing agent **202** controls the communication pathways in all the layers of the processor **200**. In an alternative embodiment, multiple routing agents **202** exist to control the communication pathways. The routing agent **202** may be a combination of hardware and software. The routing agent **202** may have several functions such as sending an enable/disable signal to one or more communication pathway switching devices and sending a signal to change various clocking speeds. The buffer layer **206** may have one or more inbound communication pathways. The buffer layer **206** may have one or more outbound communication pathways. The information transfer layer **208** may have one or more inbound communication pathways. The information transfer layer **208** may have one or more outbound communication pathways.

[0020] Figure 3 illustrates a two processor point-to-point architecture 300 having a 16-bit point-to-point connection between: 1) an input-output component 302 and the first processor 304; as well as 2) the input-output component 302 and the second processor 306. A first processor 304 having four 16-bit ports 308, 310, 312, 314 connected to the processor may have three 16-bit ports 308, 310, 312 connected to a second processor 306 and one 16-bit port connected 314 to the input-output component 302. In an embodiment, the input-output component maybe a bridge, a memory, a chipset or similar component. Thus, a 48-bit bandwidth connection exists between the first processor 304 and the second processor 306. Further, the first processor 304 and the second processor 306 have a 16-bit bandwidth connection to the input-output component 302. The routing agent can change the communication pathways in the first processor 304 such that the processor now has two 16-bit point-to-point (32-bit) connections to the second processor 306 and a 32-bit connection to the input-output component 302.

[0021] Figure 4 illustrates a two processor point-to-point architecture 400 having a 32-bit point-to-point connection between: 1) the input-output component 402 and the first processor 404; as well as 2) the input-output component 402 and the second processor 406. A first processor 404 having four 16-bit ports 408, 410, 412, 414 connected to the processor may have two 16-bit ports connected to a second processor 406 and two 16-bit ports connected to the input-output component 402 such as a chip set. Thus, a 32-bit bandwidth connection exists between the first processor 404 and the second processor 406. Further, the first processor 404 and the second processor 406 have a 32-bit bandwidth connection to the input-output component 402. In the 32-bit mode as compared to 16-bit mode, the bandwidth between the input-output component

402 and the first processor **404** as well as the input-output component **402** and the second processor **406** has effectively doubled. In 16-bit mode, eight clock cycles must occur to transfer eight 16-bit packets (128 bits) of information between each processor and the input-output component. In 32-bit mode, four clock cycles must occur to transfer four 32-bit packets (128 bits) of information between each processor and the input-output component.

[0022] Figure 5 illustrates an embodiment of a four processor point-to-point architecture **500** having a 16-bit point-to-point connection between an input-output component **502** and each of the four processors **504, 506, 508, 510**. The four processors are processor 1 **504**, processor 2 **506**, processor 3 **508**, and processor 4 **510**. In an embodiment, each of the four processors **504, 506, 508, 510** employs an embodiment of the arbiter. The processors **504, 506, 508, 510** have a flexible architecture that coordinates with the arbiter to allow a variety of uses for these processors **504, 506, 508, 510**. For example, the four processor architecture **500** may be substituted with the two processor architecture employing a 32-bit connection with the input-output component **502**. Thus, the processing power of this arrangement has effectively doubled because four processors will process the data coming from the input-output component **502**. Thus, an embodiment of the arbiter allows the same input-output component **502** to work with either a two processor architecture, a four processor architecture **500** or other similar multiple processor architecture.

[0023] A programmable knob setting in a configuration register directs the routing agent to establish the customer's current desired configuration such as a 16-bit, 32-bit, or 48-bit point-to-point connection between the processor and a device exterior to the processor. In an

routing agent **602**; a first time delay **609**, and a first flip flop **630**. The second physical layer (SPX1) **632** has a second port **634**; nine 16-bit registers, a tenth register **636**, an eleventh register **638**, a twelfth register **640**, a thirteenth register **642**, a fourteenth register **644**, a fifteenth register **646**, a sixteenth register **648**, a seventeen register **650**, and an eighteenth register **652**; a second 64-bit register **653**; and a second time delay **637**, and a second flip flop **656**. A multiplexer is a device that merges several low-speed transmissions into one high-speed transmission and vice versa. The configuration register **654** informs the routing agent **602** whether a particular component exterior to the processor should be a 16-bit, 32-bit or 48-bit-point-to-point connection.

[0026] If the configuration register **654** is programmed for a 16-bit point-to-point connection to the input-output component, then the routing agent **602** directs each physical layer to act independently of the other physical layers. In an embodiment of a four processor architecture for example, the first port **606** connects to a second processor and the second port **634** links up to an input-output component. The first register **608** receives an inbound 16-bit packet of information through the first port **606**. This 16-bit packet of information is sent from the first register **608** through a first time delay **609** to be stored in the second register **610**. The first register **608** receives another inbound 16-bit packet of information through the first port **606**. The first register **608** sends this second 16-bit packet of information to be stored in the third register **612**. The first physical layer **604** repeats this process until the second register **610** through the ninth register **624** are each storing 16-bit packets of information. The first communication pathway switching device **628** senses that these eight 16-bit (or 128-bits) of information are ready to be transferred to the first link layer through the first flip flop **630**. Upon the next clock cycle the 128-bits of

information are transferred to the first link layer through the first flip flop **630**. In a similar manner but using the components of second physical layer **632**, the second physical layer **632** transfers 128-bits to the second link layer. However, the 128-bits of information that are transferred to the first link layer are unrelated to the 128-bits of information that are transferred to the second link layer. Thus, in our example the first 128-bits of information come through the first port **606** from a second processor. Similarly, the second 128-bits of information come through the second port **634** from the input-output component. The routing agent **602** enables the 128-bit path in the first communication pathway switching device **628**. The routing agent **602** disables the dual 64-bit path in the first communication pathway switching device **628**. The routing agent **602** enables the first flip flop **630** and the second flip flop **656**.

[0027] If the configuration register **654** is programmed for a 32-bit point-to-point connection, then the routing agent **602** gangs two physical layers to act together. The routing agent **602** disables the 128-bit path in the first communication pathway switching device **628**. The routing agent **602** enables the dual 64-bit path in the first communication pathway switching device **628**. The routing agent **602** enables the first flip flop **630** but disables the second flip flop **656**. The routing agent **602** increases the clocking speed for the first register **608** through the eighteenth register **652** by a factor of two. The first physical layer **604** receives four 16-bit packets of information and stores the packets of information in the second register **610** through the fifth register **616**. The second physical layer **632** receives four 16-bit packets of information and stores the packets of information in the eleventh register **638** through the fourteenth register **644**. The first communication pathway switching device **628** senses that the first 64-bit register contains four 16-bit packets of information from the second register **610** through the fifth register

616. The first communication pathway switching device **628** senses that the second 64-bit register contains four 16-bit packets of information from the eleventh register **638** through the fourteenth register **644**. Upon the next clock cycle, the 64-bits of information from the first 64-bit register and the 64-bits of information from the second 64-bit register are transferred up to the first communication pathway switching device **628** through the dual 64-bit path. The first communication pathway switching device **628** transfers the eight related 16-bit packets of information to the first link layer. Both the device exterior to the processor and the processor transfer the eight related 16-bit packets of information as if a 32-bit point-to-point connection exists between the processor and the device. The second link layer receives no signal because the second flip flop **656** is disabled. In a similar manner, the routing agent may gang three physical layers together to create a 48-bit point-to-point connection between the processor and the device.

[0028] Figure 7 illustrates an embodiment of the routing agent **702** controlling the inbound communication pathways in an embodiment of the buffer layer **700**. The inbound communication pathway of the first link layer **704** has a first 128-bit register **706**, a first response queue **708**, a first request queue **710**, and a first communication pathway switching device **712**. The inbound communication pathway of the second link layer **714** has a second 128-bit register **716**, a second response queue **711**, a second request queue **713**, and a second communication pathway switching device **716**. The component makeup of the third link layer **718** and fourth link layer **720** are similar to the first link layer **704**. The first link layer **704** through the fourth link layer **720** feed into a fifth communication pathway switching device **722**, an embodiment of a routing

agent **702**, a fifth 128-bit register **724**, a local address transaction tracker buffer (LATT) **726**, a central data management buffer (CDM) **728**, and a remote address transaction tracker buffer (RATT) **730**.

[0029] In an embodiment of the inbound buffer layer **700**, if the configuration register **732** is programmed for a 32-bit point-to-point connection, then the routing agent **702** effectively gangs two link layers together. The first link layer **704** receives the eight related 16-bit packets (128-bit) of information at twice the clock speed from the communication switching device in the first physical layer. The first link layer **704** stores the 128-bit packet of information in the first register **706**. The 128-bit packet of information is routed appropriately to either the first response queue **708** or the first request queue **710**. The routing agent **702** sends an enablement signal to the first communication pathway switching device **712**, third communication pathway switching device **734**, and fifth communication pathway switching device **722**. The routing agent **702** also sends a disable signal to the second communication pathway switching device **716** and fourth communication pathway switching device **736**. The routing agent **702** directs the fifth communication pathway switching device **722** to request data only from the first communication pathway switching device **712** and the third communication pathway switching device **734**. In 32-bit mode, the second communication pathway switching device **716** and fourth communication pathway switching device **736** receive no signal from the physical layer because the routing agent **702** disabled the second flip flop and fourth flip flop in the physical layer.

[0030] The 128-bit packets of information are transferred to the fifth communication pathway switching device **722** through the first communication pathway switching device **712** and then the third communication pathway switching device **734** in a cyclic sequential manner. In a

repeating cycle, the fifth communication pathway switching device **722** requests the contents of the first response queue **708**, then the first request queue **710**, then the third response queue **738**, then the third request queue **740**, and then repeats this sequence. Every packet of information may be either a request for a command and/or data or a response to a command or data. In an embodiment, once a packet is written into a response queue or request queue, then the information is transferred from these queues at core clock frequency. The packets of information are sent from the fifth communication pathway switching device **722** to one of the following three components. The central data management buffer (CDM) **728** stores data to be consumed by the protocol layer **740**. The remote address transaction tracker buffer (RATT) **730** stores commands from a remote device such as a request from a remote processor. The CDM **728** stores corresponding data, if any, associated with that command. Similarly, the local address transaction tracker buffer (LATT) **726** stores local commands and responses made by the processor core. The corresponding data, if any, associated with that command is stored in the CDM **728**.

[0031] If the configuration register **732** is programmed for a 16-bit point-to-point connection, then each inbound link layer **704**, **714**, **718**, **720** acts independently. The routing agent **702** directs the fifth communication pathway switching device **722** to request information out of the eight possible sources, the corresponding request queue **710**, **713**, **740**, **750** or the corresponding response queue **708**, **711**, **738**, **748** in each link layer **704**, **714**, **718**, **720**, in a cyclic sequential manner. If a particular queue is empty, then the communication pathway switching device **722** automatically pulls packets out of the next queue without any penalty. In an embodiment, the packets from the four physical layers are written into the appropriate queue at 100 megahertz, if

layer **804** delivers commands generated from itself to the LATT **814** and data, if any, corresponding to that command to the CDM **816**. The protocol layer **804** delivers responses to commands from remote devices to the RATT **818** and data, if any, corresponding to that command to the CDM **816**. If the configuration register **820** is programmed for a 32-bit point-to-point connection, then the routing agent **802** effectively enables two of the four outbound link layers. The following happens in tracing the signal path in the first outbound link layer **806** and the second outbound link layer **808**. The routing agent **802** directs the second communication pathway switching device **822** and the fourth communication pathway switching device (not shown) to be disabled. The routing agent **802** directs the fifth communication pathway switching device **828** to request data through the first communication pathway switching device **824** and third communication pathway switching device **826** from their respective request buffer **830** or response buffer **832**. The fifth communication pathway switching device **828** alternates, in a repeating cycle, requests for bits from the request buffer **830** and the response buffer **832**. The fifth communication pathway switching device **828** also receives any data, if any, corresponding to those commands from the CDM **816**. The fifth communication pathway switching device **828** then routes the 128-bit data packet through a first time delay **833** to either the outbound response queue **836** or outbound request queue **834** located in the outbound physical layer.

[0034] One or more retry queues **838** exist in the outbound link layer. The retry queue **838** stores a duplication of the information to be transferred in case an error occurs in the transfer of the information. The retry queue **838** exists primarily in case there may be an error in the link. The retry queue **838** erases the duplicated information stored in a retry queue **838** upon receiving a confirmation of an error free transfer of information.

[0035] If the configuration register **820** is programmed for a 16-bit point-to-point connection, then the routing agent **802** directs each outbound link layer **806, 808, 810, 812** to act independently. The routing agent **802** sends a signal to enable all of the outbound link layer communication switching devices and set the clock speed to the default clock speed. The information is routed from the LATT **814**, RATT **818**, and CDM **816** through its own respective outbound link layer to the corresponding outbound physical layer. For example, the routing agent **802** directs the second communication pathway switching device **822** to request data through the sixth communication pathway switching device **840** from the second request queue **842** and then request data through the seventh communication pathway switching device **844** from the second response queue **846**. The second communication pathway switching device **822** alternates, in a repeating cycle, requests for bits from the second response queue **842** and the second request queue **846**. The second communication pathway switching device **822** also receives any data, if any, corresponding to those commands from the CDM **816**. The second communication pathway switching device **822** then routes the 128-bit data packet through a second time delay **848** to either the second outbound response queue **850** or second outbound request queue **852** located in the outbound physical layer.

[0036] Figure 9 illustrates an embodiment of the routing agent **902** controlling the communication pathways in an outbound information transfer layer **900**. In an embodiment, the information transfer layer comprises one or more physical layers. The physical layer carries out the actual physical transfer of information to devices external to the processor through ports, such as a first port **904** and a second port **906**. Typically, one 16-bit port exists on each physical layer

between the processor and the input-output component, then routing agent **902** directs each physical layer to act independently of the other physical layers. A fourth communication pathway switching device **926** reads the 32-bit packet of information at 400 megahertz from the third register **920** and outputs two 16-bit packets of information. A fifth communication pathway switching device **928** reads the 16-bit packet of information at 400 megahertz from the forth register **927** and outputs the 16-bit packet of information to the first port **904**. The routing agent **902** sends a signal to the sixth communication pathway switching device **930** in the second outbound physical layer **932**. The signal enables the 16-bit path in the fifth communication pathway switching device **928**. The routing agent **902** disables the 32-bit bypass path **922** from the fourth communication pathway switching device **926**. The routing agent **902** also sends a signal to the second physical layer **932**, the sixth communication pathway switching device **930**, to enable the 16-bit path in the sixth communication pathway switching device **930** and disable/ignore the 32-bit bypass path **922** coming from the third register **920**. Thus, the output from first port **904** and the second port **906** are unrelated 16-bit packets of information.

[0039] If in one embodiment for example, a 32-bit point-to-point connection exist between the processor and the input-output component, then the routing agent **902** gangs the output of the first port **904** and the output of the second port **906**. The routing agent **902** sends a signal to the sixth communication pathway switching device **930**. The routing agent's signal disables the 16-bit path in the sixth communication pathway switching device **930** and enables the 32-bit bypass path **922** coming from the third register **920**. The routing agent **902** also sends a signal to the first physical layer **931**, the fourth communication pathway switching device **926**, to enable the 32-bit bypass path **922**. Thus, the output from first port **904** and the second port **906** are related

the buffer layer, and the information transfer layer may be combined, for example, on a single layer or transported to another component. The invention should be understood to not be limited to the particular forms disclosed, but on the contrary, the intention is to cover all modifications, equivalents, and alternatives falling within the spirit and scope of the invention as defined by the appended claims.
